***Abstract*—Hospitals coordinate many connected activities, including patient registration, appointment scheduling, clinical documentation, laboratory requests, pharmacy operations, bed allocation and billing. When these activities are handled through paper files or disconnected software, staff may need to enter the same information repeatedly, patient information can become difficult to retrieve, and managers may lack a current view of hospital resources. This paper proposes a Smart Hospital Management System (SHMS), a role-based web platform intended to bring major administrative and clinical workflows into one coordinated system. The proposed design includes patient registration, appointment and queue management, electronic patient records, doctor and staff scheduling, bed and ward management, laboratory and pharmacy workflows, billing, notifications and administrative reports. Access is controlled according to user roles, while audit records capture important actions. The system is designed around a central application layer and a structured database, with interfaces that can be extended to support healthcare data exchange standards. The work is organized into a study of existing hospital information workflows, system and database design, and a prototype implementation plan. Since this paper describes a proposed system, performance improvements are expected outcomes and must be confirmed through implementation and user evaluation. The proposed platform aims to reduce administrative duplication, improve information availability and support more coordinated hospital operations.**

***Index Terms*—Appointment Scheduling, Electronic Health Record, Hospital Information System, Patient Management, Smart Hospital, Workflow Automation.**

I. INTRODUCTION

Hospitals are complex service organizations in which clinical teams, administrative staff, laboratories, pharmacies and support departments must coordinate continuously. A patient's journey may begin with registration and appointment booking, continue through consultation and diagnostic testing, and end with treatment, billing and discharge. Each stage generates information that is useful to other departments. If the information is recorded in separate registers or isolated applications, staff may face delays in locating records, duplicate data entry and difficulty tracking the current status of a patient or service.

Digital health systems can support more organized and accessible healthcare information when they are planned around people, processes, privacy and interoperability [1]. In India, the Ayushman Bharat Digital Mission (ABDM) promotes a connected digital health ecosystem and supports the creation and consent-based sharing of digital health records [2]. Standards such as HL7 Fast Healthcare Interoperability Resources (FHIR) provide a common way for healthcare applications to exchange structured information [3]. These developments provide a relevant context for designing hospital systems that can work with other digital health services.

This paper proposes a Smart Hospital Management System that integrates essential hospital workflows through a unified application. Its main contributions are: (1) identification of common operational problems in fragmented hospital workflows; (2) a modular architecture and database model for core hospital services; and (3) a prototype-oriented workflow that connects patient registration, appointments, clinical records, diagnostics, pharmacy, beds and billing.

II. LITERATURE SURVEY

Digital health programmes increasingly emphasize the availability and responsible exchange of health information. The World Health Organization's global strategy on digital health highlights the need for coordinated investment in governance, infrastructure, workforce and appropriate digital technologies [1]. This indicates that a hospital information system

should not be treated only as a software installation; its success also depends on processes, training and organizational readiness.

In India, ABDM provides building blocks such as the Ayushman Bharat Health Account (ABHA), Health Facility Registry and Healthcare Professionals Registry. The programme is intended to support interoperable digital health services and consent-based access to health records [2]. A hospital management platform can be designed with future integration in mind, while ensuring that any actual connection follows applicable ABDM specifications and approval processes.

HL7 FHIR defines resources and exchange patterns for representing and sharing healthcare information, including administrative, clinical, diagnostic and medication-related data [3]. At the operational level, hospital information systems commonly bring together patient registration, outpatient and inpatient workflows, electronic records, laboratory, radiology, billing and pharmacy functions. India's National Informatics Centre describes these types of modules in its NextGen eHospital initiative [4].

The proposed system differs in emphasis by presenting these functions as a modular workflow for a hospital-level prototype. It focuses on a consistent patient identity, role-based access, shared operational status and traceable updates. The design does not claim to replace national health platforms or certified hospital systems.

III. PROBLEM STATEMENT AND OBJECTIVES

A. Problem Statement

In hospitals where departments use manual registers or disconnected applications, patient details and service information may be repeated across departments. Appointment queues, doctor availability, bed occupancy, diagnostic requests, pharmacy issues and billing status may not be visible from one coordinated interface. This can create avoidable administrative effort, slow information retrieval and make it difficult for management to obtain timely operational reports. Sensitive patient information also requires controlled access and accountability for viewing or modification.

B. Objectives

1) To maintain a consistent digital record for patient registration and basic demographic details.
2) To support appointment booking, doctor schedules and outpatient queue status.
3) To organize clinical notes, prescriptions, laboratory requests and diagnostic results.
4) To manage bed availability, admission, transfer and discharge workflows.
5) To coordinate pharmacy inventory, medicine issue records and billing information.
6) To provide role-based access, audit trails and administrative reports.
7) To design the system so that standards-based interoperability can be considered in future development.

IV. PROPOSED METHODOLOGY

The proposed work is divided into three phases. Each phase produces an output required by the next phase.

A. Phase 1: Study of Existing Hospital Workflows

Common workflows are identified by examining the information handled by reception, doctors, nurses, laboratory staff, pharmacists, billing staff and administrators. For each workflow, the required inputs, responsible user, output and hand-off to the next department are documented. The study focuses on repeated data entry, delays in locating information, lack of shared status and access-control requirements.

B. Phase 2: System Architecture and Database Design

A modular architecture is designed with a user interface, application services and a relational database. Users sign in through an authentication service. The application checks their role and permissions before allowing an operation. Validated records are stored in the database, and important create, update, view or approval actions are recorded in an audit log. Interfaces are separated by module so that appointment, clinical, laboratory, pharmacy, bed and billing functions can be developed and tested independently.

C. Phase 3: Prototype Development and Testing

A prototype can be developed as a responsive web application. The initial build should implement

patient registration, appointment scheduling, doctor availability, patient visit records and basic billing before adding laboratory, pharmacy and inpatient modules. Testing should use synthetic patient data rather than real identifiable health information. Functional tests verify each workflow, while usability tests assess whether staff can complete common tasks accurately.

V. SYSTEM ARCHITECTURE

The system follows a layered architecture. Patients and authorized hospital staff interact with the presentation layer. The application layer validates requests, applies business rules and enforces role permissions. The data layer stores patient, appointment, visit, staff, bed, diagnostic, medicine and billing records. An audit service records significant actions. An optional interoperability interface can later map selected data to recognized healthcare exchange formats such as FHIR, subject to institutional and regulatory requirements.

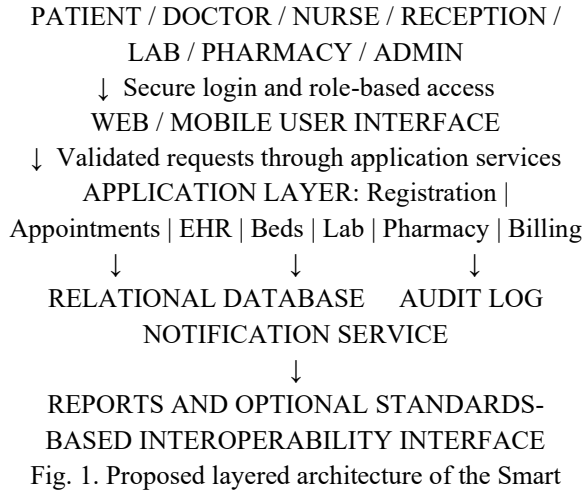

Fig. 1. Proposed layered architecture of the Smart Hospital Management System.

A. Stakeholders and Roles

Administrator: creates staff accounts, assigns roles, configures departments and reviews operational reports. Receptionist: registers patients, books appointments and manages queues. Doctor: views assigned appointments, reviews relevant patient history, records consultation notes and issues prescriptions or test requests. Nurse: records permitted observations and supports admission and ward workflows. Laboratory staff: receives test requests, updates test status and enters verified results. Pharmacist: manages medicine stock and records medicine dispensing. Billing staff: prepares invoices and records payments. Patient: may view permitted appointment information and personal records through a patient-facing interface.

B. Main Data Model

The database is organized around a unique patient identifier. Each visit is linked to the patient and may contain consultation notes, prescriptions, diagnostic requests and billing entries. Access permissions determine which roles can read or update each category.

Entity	Key attributes
Patient	Patient ID, name, date of birth, contact, address, optional ABHA reference
Staff	Staff ID, name, department, role, qualification, schedule
Appointment	Appointment ID, patient ID, doctor ID, date, time, status
Visit / EHR	Visit ID, patient ID, doctor ID, symptoms, notes, diagnosis, date
Diagnostic	Request ID, visit ID, test type, status, result, verification date
Medicine	Medicine ID, name, batch, expiry date, stock quantity, reorder level
Bed / Admission	Bed ID, ward, availability, admission ID, patient ID, dates
Invoice	Invoice ID, patient ID, visit/admission ID, item details, amount, payment status
Audit Log	Log ID, user ID, action, record type, timestamp, outcome

C. Core Workflow

1) Reception creates or retrieves the patient's record and assigns a patient identifier.

2) The patient books an appointment; the system checks the selected doctor's schedule and records the booking.

3) During consultation, the doctor reviews permitted history and records notes, diagnosis and treatment instructions.

4) If required, a diagnostic request is sent to the laboratory; the result is attached to the relevant visit after verification.
5) A prescription is made available to the pharmacy, where dispensing and stock updates are recorded.
6) For inpatient care, authorized staff allocate a bed and record admission, transfer and discharge events.
7) Billing staff generate an invoice from applicable services and record payment status.
8) The system stores an audit entry for significant actions and updates the relevant operational status.

VI. SECURITY, PRIVACY AND INTEROPERABILITY

Hospital records contain sensitive personal and clinical information. The proposed system therefore applies least-privilege access: each user receives only the permissions required for their work. Authentication, secure transport, protected backups, session management and audit logging should be included. Patient information should not be exposed in public reports, and development and testing should use synthetic or appropriately de-identified data. Data retention, consent, breach response and access procedures must be aligned with applicable Indian laws, institutional policy and relevant health-data requirements.

The system should use a consistent internal data model and avoid hard-coding interfaces to a single external provider. If interoperability is implemented, FHIR resources and applicable ABDM specifications may guide the exchange of patient, practitioner, organization, encounter, observation and medication information [2], [3]. Integration is a future capability in this proposal, not a claim that the prototype is already connected to ABDM.

VII. EXPECTED RESULTS AND DISCUSSION

The expected outcome is a unified prototype through which authorized users can access the modules relevant to their responsibilities. Compared with disconnected registers, the proposed workflow is expected to reduce repeated entry of basic patient information and make appointment, bed, diagnostic and billing status easier to locate. Role-based permissions and audit records are expected to improve accountability for access and changes. These benefits are design expectations and must be measured during prototype evaluation.

Evaluation area	Proposed measure	Expected direction
Registration	Time to register a test patient; duplicate-record rate	Lower time and fewer duplicates
Appointments	Booking time; schedule conflicts; queue visibility	Fewer conflicts and clearer status
Records	Time to retrieve a permitted visit record	Faster retrieval
Inpatient	Accuracy of bed-occupancy status	More current status
Pharmacy	Stock-record accuracy; low-stock alerts	Improved stock visibility
Security	Role-permission test pass rate; audit completeness	Controlled access and traceability
Usability	Task completion rate and staff feedback	Improved ease of use

A prototype evaluation should measure task completion time, error rate, record retrieval time, appointment conflicts and user feedback using a defined test dataset. The study should report actual measurements only after testing. The system also has limitations: data quality depends on correct entry; network or power interruptions can affect access; staff training is necessary; and integration with legacy systems may require additional mapping and governance. A hospital deployment would require security assessment, clinical workflow validation, backup and recovery testing, and formal approval by the institution.

VIII. CONCLUSION AND FUTURE SCOPE

This paper proposed a Smart Hospital Management System that coordinates patient registration, appointments, electronic visit records, diagnostics, pharmacy, bed management and billing through a modular web-based platform. The design uses a

shared patient identifier, role-based permissions and audit records to support coordinated workflows and accountable access. It also considers future interoperability with healthcare data standards and India's digital health ecosystem. The paper presents a proposed design and evaluation plan; it does not claim measured improvements from a completed hospital deployment.

Future work includes implementing and evaluating the prototype with synthetic data, adding a patient mobile application, integrating laboratory and imaging systems, supporting multilingual interfaces, enabling appointment reminders, adding analytics for resource planning and exploring standards-based exchange with ABDM. Any clinical decision-support feature should be separately validated and must not replace professional medical judgement.
