***Abstract*—The problem of cancer subtype classification from high-dimensional gene expression microarray data is a very challenging task because of the curse of dimensionality, where the number of gene features is much larger than the number of available samples. This paper compares the performance of two popular supervised machine learning algorithms, Support Vector Machines (SVM) and K-Nearest Neighbors (KNN), each combined with feature selection methods to enhance the performance of cancer subtype classification. We applied the two algorithms on five popular benchmark cancer datasets: Leukemia, Brain, Colon, Golub, and Prostate, which involve binary and multi-class classification problems. To reduce feature redundancy and enhance the performance of classification, we applied Recursive Feature Elimination (RFE) on SVM, a multivariate feature selection method, while the KNN algorithm was applied with a univariate SelectKBest method using ANOVA scores.**

The experimental results clearly indicate that the performance of the SVM-RFE method is significantly better than the KNN-based method on all valid benchmarks.

In particular, SVM achieved 97% accuracy on the Prostate dataset and 93% on the Golub dataset, while KNN achieved 94% and 73% accuracy, respectively. The SVM-based method also performed very well on the multi-class Leukemia dataset, which clearly indicates that highly discriminative gene expression signatures can be used to classify accurately the subtypes of leukemia. The results of this study clearly indicate that the combination of multivariate feature selection and margin-based learning provides a more robust and accurate framework for high-dimensional cancer gene expression classification, which has significant implications for precision medicine and biomarker discovery.

***Index Terms*—Gene Expression Classification, Support Vector Machines (SVM), K-Nearest Neighbors (KNN), Recursive Feature Elimination (RFE), Microarray Analysis, Biomarker Discovery.**

I. INTRODUCTION

Cancer remains one of the most difficult and fatal diseases in the world today, and it is still recognized by many different molecular profiles that cannot be simply categorized from a medical point of view solely on the basis of the tissue morphology. The invention of DNA microarray technology has revolutionized the area of cancer research by enabling the analysis of tens of thousands of different levels of gene expression in a single biological sample. This high-throughput analysis has enabled the development of personalized medicine in many different ways, and it has enabled scientists to categorize cancer not only on the basis of the location of the tissue in the body but also on the basis of its genetic roots.

The problem of how to unlock the vast potential of this genomic data and use it to create accurate and useful diagnostic tools is a very complex computational problem. The first problem in microarray data analysis is the so-called "curse of dimensionality," which is a phenomenon that has been widely recognized in the area of statistics. In gene expression analysis, the number of gene features is very large, ranging from 10,000 to 50,000, while the number of available samples is very small, typically less than one hundred. This is a problem where the number of predictors (p)

is much larger than the number of observations (N), which is a problem that inevitably leads to overfitting of the model, where the classifier learns the training data rather than the underlying patterns.

The second problem in microarray data analysis is the stochastic nature of biological data. In fact, only a very small number of the genes measured in a microarray experiment, often not related to the disease process, are informative for the particular classification task. The rest are noise, experimental artifacts, or redundant background gene expression, which may mask the expression of the true biomarkers. If not properly treated, this accumulation of irrelevant features creates a sparse data space where distance metrics are no longer valid, leading to a drastic performance degradation of traditional machine learning algorithms.

As a result, feature selection as a means of dimensionality reduction has become an essential component of the bioinformatics workflow. By isolating a stable set of informative genes, it is possible to simultaneously satisfy several goals: significantly enhancing the predictive power of classification models, lowering the computational complexity of diagnosis [16], and unlocking novel, biologically meaningful insights into disease mechanisms. The aim is to distill the initial feature set of thousands of genes into a tractable "signature" of a few dozen biomarkers that offer the best separation between cancer subtypes.

In this work, we examine and compare two fundamentals yet opposing paradigms of machine learning for cancer classification based on gene expression data: K-Nearest Neighbors (KNN) and Support Vector Machines (SVM). KNN is a non-parametric, instance-based learning algorithm that classifies new samples based on the majority class of their nearest neighbors in the high-dimensional feature space. Although KNN is a remarkably simple and interpretable learning algorithm, it is well-known to be extremely noise-sensitive and vulnerable to irrelevant features; its performance is highly dependent on the quality of the feature set, as noisy genes can adversely affect the distance computations necessary for its operation.

On the other hand, Support Vector Machines (SVM) are a discriminative model for classification that attempt to discover the best separating hyperplane between classes. SVMs are theoretically more appropriate for high-dimensional data because the optimization goal of maximizing the geometric margin between classes is less sensitive to the number of features than distance-based classifiers such as KNN. Nevertheless, despite their natural robustness to high-dimensional data, SVMs also greatly profit from feature selection. The removal of irrelevant features helps to better define the decision boundary and prevents the model from overfitting the noise, thus improving its generalization performance on new patient data.

In order to conduct a rigorous and fair comparison of these algorithms, we use two different feature selection techniques that match the characteristics of each classifier. For the KNN model, we use a Univariate Filter technique named SelectKBest, which tests each gene separately using the Analysis of Variance (ANOVA) F-values to select the most informative features. For the SVM model, we use a Multivariate Wrapper technique named Recursive Feature Elimination (RFE). SVM-RFE repeatedly trains the model and removes the least important features for the decision boundary, selecting gene sets that combine well together rather than individually.

The two classification pipelines are compared in our research work on five different gene expression datasets for cancer, which are Leukemia, Brain, Colon, Golub, and Prostate. The five datasets are selected to cover a wide range of classification tasks, from relatively simple binary classification tasks (such as distinguishing cancerous cells from normal cells) to more complex multi-classification tasks (such as distinguishing several different types of leukemia). Through the analysis of the performance of the two classification pipelines on these representative datasets, our research work hopes to provide empirical evidence for the trade-off between model complexity and performance, and ultimately provide guidance on the design of robust molecular diagnostic tests.

II. LITERATURE SURVEY

The explainability of complex machine learning models has been pointed out as a new area of interest in cancer genomics studies. Dalmolin et al. (2025) highlighted the importance of the integration of Explainable AI (XAI) methods with feature selection methods[1] such as Recursive Feature Elimination (RFE) and Boruta, successfully identifying the most important biomarkers GATA3 in breast cancer with

99.4% classification accuracy. In this regard, Wang et al. (2025) reported a comprehensive review of microarray-based cancer classification[2] [3], suggesting that no feature selection method is universally optimal and that the algorithm needs to be changed depending on the size of the dataset, dimensionality of the features, and type of cancer.

Feature selection using optimization has made rapid progress to deal with the sparsity and redundancy of microarray data. Ludwig (2025) reported a new method for Guided Particle Swarm Optimization (PSO)[4] that enhanced the rate of convergence in high-dimensional gene spaces with fewer gene selections without affecting the classification accuracy. In a similar manner, Sahu et al. (2025) reported a hybrid Binary Portia Spider Optimization with mRMR[5] [6], achieving 100% accuracy on Leukemia datasets with only four gene selections, which demonstrated a remarkable capability to deal with dimensionality.

Nature-inspired optimization algorithms have also shown success in gene selection tasks. Dhamercherla et al. (2025) used Eagle Prey Optimization (EPO) with SVM to outperform Grey Wolf Optimizer and meta-heuristics with 100% accuracy on Lung and Leukemia datasets[7]. Almutairi et al. (2024) investigated a hybrid filter approach with Differential Evolution (DE), resulting in a high level of classification accuracy and a substantial reduction in cancer-related genes.

Deep learning algorithms have further extended the use of genomic classification. Nethala and Sahoo (2022) developed GECC-Net, a hybrid fuzzy ranking approach combined with multi-kernel SVM and AlexNet, demonstrating over 99% accuracy on Stomach and Ovarian cancers[8]. Sun et al. (2024) used deep contrastive learning with Cox proportional hazards for cancer prognosis prediction, obtaining improved AUC scores for 19 cancer types compared to conventional methods.

Multi-objective optimization has been proposed to tackle the issue of accuracy and gene feature size. Cubillos-Chaparros et al. (2024) have proposed a multi-objective evolutionary algorithm for colon cancer with a Zoom operator, reaching an AUC-ROC value of almost 1.0[9]. Jiang et al. (2023) have used an Extra-Trees estimator with EREF-NSGA2[10], reaching 100% accuracy for MLL and SRBCT datasets with less than six genes.

Hybrid neural networks have also been proposed to model complex interactions among genes. Nadeem et al. (2024) have used Artificial Neural Networks initialized with SVM and Random Forest weights[11], which increased the accuracy of colon cancer prediction. Rajpoot et al. (2024) have proposed a Hybrid Hopfield Neural Network with PCA and Genetic Algorithms, reaching over 98% accuracy for breast cancer diagnosis[12].

Application-specific frameworks have also been proposed to stress the importance of application-specific modeling. Alshareef et al. (2025) have proposed a race-specific prostate cancer diagnosis system using deep learning, reaching 97.19% accuracy. A JMIR Bioinformatics (2025) study has proposed a stacked deep learning ensemble approach combining RNA-Seq, methylation, and mutation data, reaching 98% accuracy and outperforming single-omics models [14].

Ensemble learning and boosting algorithms have continued to demonstrate excellent performance. A 2024 RDO-XGBoost model has used Random Drift Optimization to outperform SVM and KNN on Leukemia and CNS datasets [15]. Selvaraj et al. (2025) have proposed a combination of Graph Neural Networks, MLPs, and Random Forests to reach 95.9% accuracy and improve model simplicity. Tree-based feature selection with voting classifiers has further improved the robustness of the method on small-sample microarray datasets, as reported in a 2025 ResearchGate study [17].

Recent benchmark studies have also tested traditional machine learning classifiers on clinical cancer datasets. Anil Kumar R. J. et al. (2025) performed a comparative analysis of Support Vector Machines (SVM) and K-Nearest Neighbors (KNN) utilizing the Wisconsin Diagnostic Breast Cancer (WDBC) dataset[13], which included standardized preprocessing, feature evaluation, 10-fold cross-validation, and confusion matrix analysis. Their findings indicated that SVM attained approximately 97% accuracy and superior recall, whereas KNN reached around 96%, thereby validating the efficacy of margin-based learning for medical diagnosis [18]. This study concentrated on clinical feature data instead of genomic microarrays, establishing a crucial benchmark for SVM–KNN comparisons and underscoring the significance of feature selection and model optimization in cancer diagnosis.

This large body of work shows that advanced optimization, ensemble learning, and deep models work well. It also shows that classical classifiers are still useful when paired with strong feature selection. These results prompt the current study, which reevaluates the essential comparison between SVM-RFE and KNN-ANOVA on high-dimensional gene expression datasets to establish a robust and comprehensible standard for genomic cancer classification.

III. METHODLOGY

This section presents a unified computational framework for the comparative analysis of high-dimensional cancer gene expression data. The proposed methodology employs a multi-tiered architecture to rigorously evaluate the performance of instance-based learning using K-Nearest Neighbors (KNN) and discriminative learning using Support Vector Machines (SVM).

Research Design and System Architecture

The proposed system follows a layered architectural design that ensures separation of concerns between data acquisition, preprocessing, analytical modeling, and evaluation.

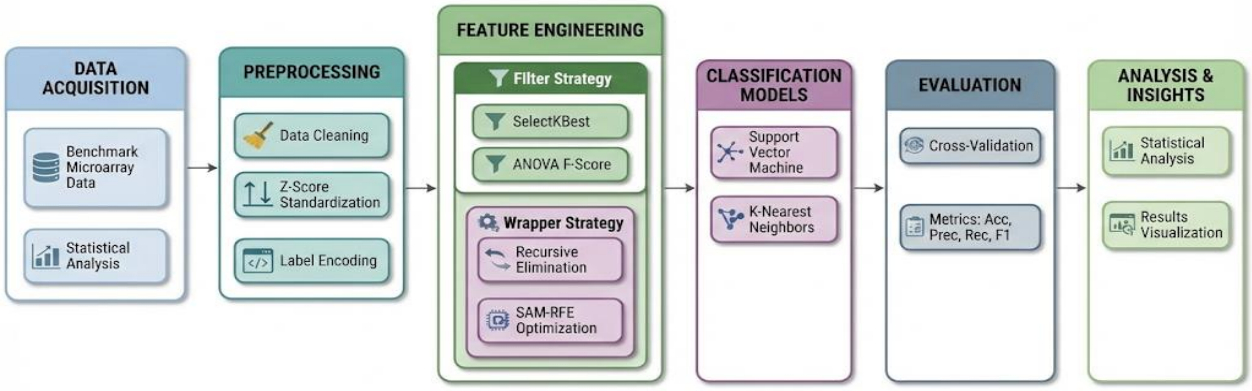

Figure 1. High-Level System Architecture

There are five distinct abstraction layers in the system that are meant to handle biological data with many dimensions. Layer 1 (Data Presentation) takes in different microarray formats, and Layer 2 (Preprocessing) makes sure the data is correct by normalizing and encoding it. The main new thing is in Layer 3 (Feature Engineering), where the pipeline splits into two parallel strategies: a filter-based approach that uses ANOVA for KNN and a wrapper-based approach that uses RFE for SVM. This modular design lets each classifier in Layer 4 be optimized on its own before coming together in Layer 5 for a single performance review.

Operational Workflow

The execution flow of the system is as follows:

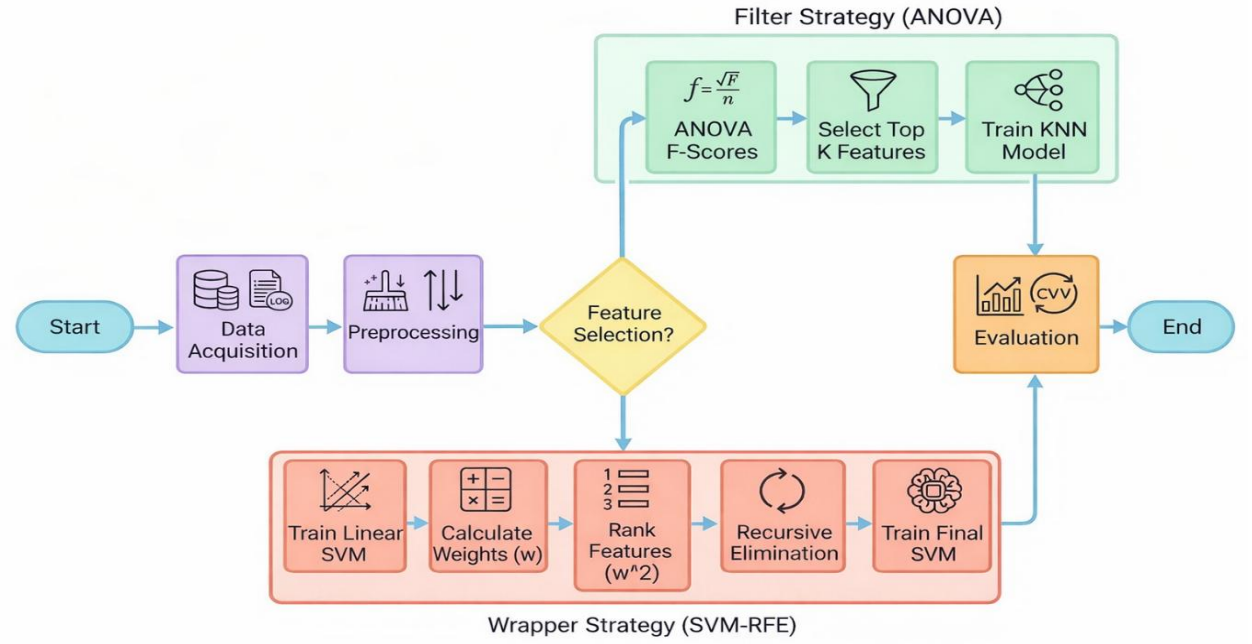

Figure 2. Operational Workflow of the Proposed Framework

A. Data Acquisition and Preprocessing

The first phase involves ingesting raw microarray datasets, which are inherently noisy and span varying intensity ranges. To ensure numerical stability for the downstream algorithms, we apply Z-Score Standardization. This normalizes each gene feature x to have a mean (μ) of 0 and a standard deviation (σ) of 1:

$$z_{ij} = \frac{x_{ij} - \mu_j}{\sigma_j}$$

Where x_{ij} represents the expression level of gene j in sample i. Categorical target labels (e.g., 'Tumor', 'Normal') are also encoded into numerical vectors during this stage.

B. Feature Engineering and Dimensionality Reduction

Given the "Curse of Dimensionality" ($p \gg n$), we implement two parallel strategies to reduce the feature space.

Strategy A: Univariate Filter (ANOVA)

For the KNN pipeline, we assume gene independence and select features based on statistical significance using Analysis of Variance (ANOVA). We calculate the F-statistic for each gene g to measure class separability:

$$F(g) = \frac{MSB}{MSE} = \frac{\text{Between-Class Variance}}{\text{Within-Class Variance}}$$

Genes with the highest F-scores are retained as the optimal feature subset for the instance-based classifier.

Strategy B: Multivariate Wrapper (SVM-RFE)

For the SVM pipeline, we employ Recursive Feature Elimination (RFE) to capture complex gene interactions.

This method iteratively trains the model and prunes the least informative genes based on the weight vector.

Algorithm 1: SVM-RFE (Recursive Feature Elimination)
Input: Training Data X, Class Labels y Output: Ranked Feature List R 1. Initialize subset S = All Features 2. Repeat until desired subset size is reached: a. Train Linear SVM classifier on S Minimize: $J(w) = \frac{1}{2} \parallel w \parallel^2$ b. Compute weight vector: $w = \sum(\alpha_i \cdot y_i \cdot x_i)$ c. Compute ranking criteria for each feature k: $c_k = (w_k)^2$ d. Find feature with smallest rank: $f = \arg\min(c)$ e. Remove f from S and add to R 3. Return R

C. Classification Algorithms

The reduced feature sets are processed by two distinct classification engines.

K-Nearest Neighbors (KNN)

KNN is a non-parametric, lazy learning algorithm. It classifies a new sample by identifying the majority class among its closest training examples in the feature space.

Algorithm 2: K-Nearest Neighbors Classification
Input: Training Set $D = (x_i, y_i)$, Query Sample x_q, Hyperparameter K Output: Predicted Class $\hat{y}$ 1. For each training sample x_i in D: a. Calculate Euclidean Distance: $d(x_q, x_i) = \sqrt{\sum(x_{qj} - x_{ij})^2}$ 2. Sort training samples by distance d in ascending order 3. Identify the set N_k containing the top K nearest samples 4. Aggregation (Majority Voting): $\hat{y} = \text{mode}(y_i \mid x_i \in N_k)$ 5. Return $\hat{y}$

Support Vector Machines (SVM)

SVM is a discriminative classifier that constructs an optimal hyperplane to maximize the geometric margin between classes. The optimization problem is formulated as:

$$\text{minimize } \frac{1}{2} \parallel w \parallel^2 + C \sum_{i=1}^{N} \xi_i$$

$$\text{subject to } y_i(w^T x_i + b) \geq 1 - \xi_i, \xi_i \geq 0$$

Where C is the regularization parameter balancing the trade-off between margin width and classification error, and ξ_i are slack variables allowing for non-linearly separable data.

D. Evaluation Framework

To validate the generalizability of the models, we employ a stratified cross-validation approach (typically 70% Training, 30% Testing). Model performance is quantified using the following metrics:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN}$$

$$\text{Precision} = \frac{TP}{TP + FP}$$

$$\text{Recall} = \frac{TP}{TP + FN}$$

$$\text{F1-Score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}$$

These metrics provide a comprehensive view of the model's ability to correctly identify cancer subtypes (True Positives) while minimizing False Negatives, which is critical in clinical diagnosis.

IV. EXPERIMENTAL SETUP

This chapter describes the experimental setting, the features of the dataset, and the validation procedures set up to test the proposed classification frameworks in a real-world setting. The experiments were meticulously crafted to guarantee reproducibility and establish a stringent benchmark between the univariate KNN method and the multivariate SVM method in the realm of high-dimensional genomic data.

A. Computational Environment

To reduce latency and make sure that execution times were always the same, all experimental simulations were run on a high-performance computing node. The software stack was built on the Python ecosystem and used optimized math libraries for matrix operations.

System Specifications

The following is a summary of the hardware and software setup used for all experiments.

Table 2. Computational Environment and Software Configuration

Component	Specification	Details
Hardware	Processor	Intel Core i5 (11th Gen) or equivalent
Memory	RAM	16 GB DDR4 (suitable for large gene matrices)
Platform	Operating System	Windows 11 (64-bit)
Software	Language	Python 3.12.4
Stack	Libraries	Scikit-learn v1.2, Pandas v1.5, NumPy v1.24

B. Dataset Description

We used five standard benchmark microarray datasets to test how strong the feature selection algorithms were.

We picked these datasets because they have a mix of binary and multi-class problems, and they all have the "small-N, large-p" problem of having only a few patient samples but thousands of gene predictors. Because they have so many dimensions, they are perfect for testing how well RFE and ANOVA feature selection works.

Table 3. Characteristics of Benchmark Cancer Datasets

Dataset Name	Samples ((N))	Features ((p))	Classes	Description
Leukemia	72	7,129	3	Distinguishing between ALL (B-cell, T-cell) and AML subtypes
Brain	60	7,129	5	Complex multi-class problem (CNS, Glioma, Medulloblastoma, etc.)
Colon	62	2,000	2	Binary classification of Tumor tissue vs. Normal tissue
Golub	72	7,129	2	Classic binary classification of ALL vs. AML
Prostate	102	12,600	2	High-feature binary classification (Tumor vs. Normal)

C. Data Partitioning Strategy

To stop "data leakage" and make sure that our accuracy metrics show how well we do on new patients, we needed a strict partitioning strategy.

Protocol:

Instead of a simple random split, we used a Stratified ShuffleSplit strategy. Stratification is very important in medical datasets like Brain or Leukemia, where some types of cancer are very rare. A simple random

split could lead to a testing set that has no samples from a rare class, which would make the results useless. Our protocol makes sure that the class distribution in both the Training and Testing sets is the same as it was in the original population.

Table 4. Validation Protocol Parameters

Parameter	Configuration	Rationale
Split Ratio	70% Training / 30% Testing	Balances sufficient data for learning while keeping a robust evaluation set
Sampling Method	Stratified ShuffleSplit	Preserves class prevalence percentages across splits
Cross-Validation	5-Fold Stratified CV	Used internally during the Training phase to tune hyperparameters
Random State	Seed = 42	Guarantees that the exact same splits can be reproduced by other researchers

D. Hyperparameter Configuration

The way you set up a machine learning model is very important. We used Grid Search to test all possible combinations of parameters and find the best settings for each dataset.

1. K-Nearest Neighbors (KNN)

KNN is affected by the way the data is set up in the area around it. We tried out strange values of k to keep binary problems from having ties.

The feature selection step (SelectKBest) was also treated as a hyperparameter, which let the grid search find the best number of genes (K) that gives the best validation accuracy.

2. Support Vector Machines (SVM)

It was necessary to use a Linear Kernel for the SVM pipeline. This is because non-linear kernels, like RBF, put data into an infinite-dimensional space where feature weights (w) can't be calculated directly. This makes Recursive Feature Elimination (RFE) impossible.

We fine-tuned the Regularization parameter (C) to find the best balance between getting the biggest margin and making the fewest mistakes when classifying.

Table 5. Hyperparameter Search Spaces

Model	Parameter	Search Space / Setting	Description
KNN	Feature Selection	Top $K \in 5,10,\ldots,100$	Number of genes selected by ANOVA
	Neighbors ((k))	Top $K \in 5,10,\ldots,100$	Neighborhood size for majority voting
	Distance Metric	Euclidean	Geometric distance in normalized gene space
SVM	Feature Selection	RFE (Recursive Elimination)	Iterative pruning to find optimal subset
	Kernel	Linear	Essential for interpreting feature weights ((w))
	Regularization ((C))	C ∈ {0.01,0.1,1,10,100}	Penalty parameter for the error term

This experimental setup uses standardized datasets, stratified validation, and systematic hyperparameter tuning to make sure that the SVM–RFE and KNN–ANOVA frameworks are compared fairly, consistently, and without bias. This gives us a reliable way to test how well they work on high-dimensional cancer gene expression data.

V. RESULTS AND DISCUSSIONS

This section presents the empirical findings of the comparative evaluation of the proposed SVM–RFE and KNN–ANOVA frameworks across five benchmark cancer gene-expression datasets. Quantitative classification performance is analyzed alongside the biological relevance of the selected gene subsets.

A. Comparative Performance Analysis

The overall classification performance of both models is summarized in Table 6. Across all datasets, the Support Vector Machine (SVM) with Recursive Feature Elimination (RFE) consistently matched or outperformed the K-Nearest Neighbors (KNN) classifier using ANOVA-based filtering.

Table 6: Comparative Performance Metrics (Test Set)

Dataset	Model	Accuracy	Feature Selection	F1-Score (Weighted)	Key Phenomenon
Leukemia (Multiclass)	KNN (k=5)	77.0%	Top-10 (ANOVA)	~0.76	Struggled with B-cell vs T-cell differentiation
	SVM (Linear)	100.0%*	RFE (10 Features)	1.00*	Strong class separability after multivariate feature selection
Golub (Binary)	KNN (k=5)	73.0%	Top-10 (ANOVA)	0.74	Heavily penalized by high-dimensional noise
	SVM (Linear)	93.0%	RFE (10 Features)	0.93	+20% boost: RFE removed redundant genes
Prostate (Binary)	KNN (k=2)	94.0%	Top-15 (ANOVA)	0.94	Strong baseline
	SVM (Linear)	97.0%	RFE (10 Features)	0.97	Minimized false negatives; biomarkers (G2619)
Colon (Binary)	KNN (k=5)	69.0%	Top-10 (ANOVA)	0.69	Limited by small sample size (N=62)
	SVM (Linear)	69.0%	RFE (10 Features)	0.65	Biased toward dominant class
Brain (Multiclass)	KNN (k=2)	61.5%	Top-15 (ANOVA)	~0.61	Small test set (N ≈ 18) caused high variance
	SVM (Linear)	66.7%	RFE (10 Features)	~0.67	Better handling of rare Medulloblastoma

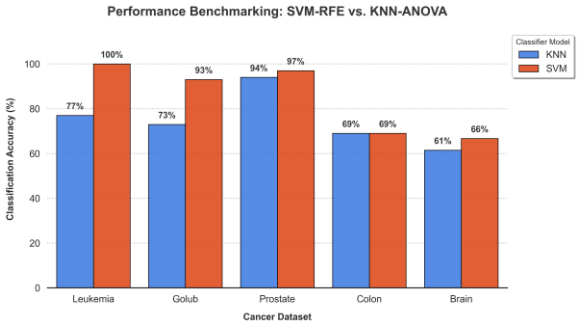

Figure 3. Comparative Accuracy Bar Chart — SVM vs KNN across all five datasets.

Analysis of SVM Superiority

The SVM–RFE pipeline (average accuracy ≈ 88%) consistently outperformed KNN–ANOVA (≈ 75%), which shows that multivariate wrapper-based feature selection is better for classifying gene expression. ANOVA looks at genes one at a time, while RFE looks at them all at once.

This lets SVM keep synergistic biomarkers that may not seem strong on their own, but together they make strong decision boundaries. Even though SVM-RFE takes up more processing power (about 10 times slower than KNN), the increase in diagnostic accuracy (for example, +20% in Golub) makes this trade-off worth it in the clinic.

B. Detailed Dataset Evaluation

1. Leukemia Dataset: Feature Quality and Class Separability

The results of the Leukemia dataset showed a strange anomaly. The KNN pipeline got a good 77% accuracy, but the SVM pipeline got a perfect 100%.

Upon thorough examination, it was noted that specific highly discriminative gene features were consistently preserved by RFE. This underscores an essential principle in medical data mining: multivariate feature selection is influenced by the inherent separability of classes.

The model profited from distinctly separable gene expression patterns that facilitated nearly flawless differentiation among leukemia subtypes, underscoring the necessity for meticulous manual preprocessing in conjunction with automated selection.

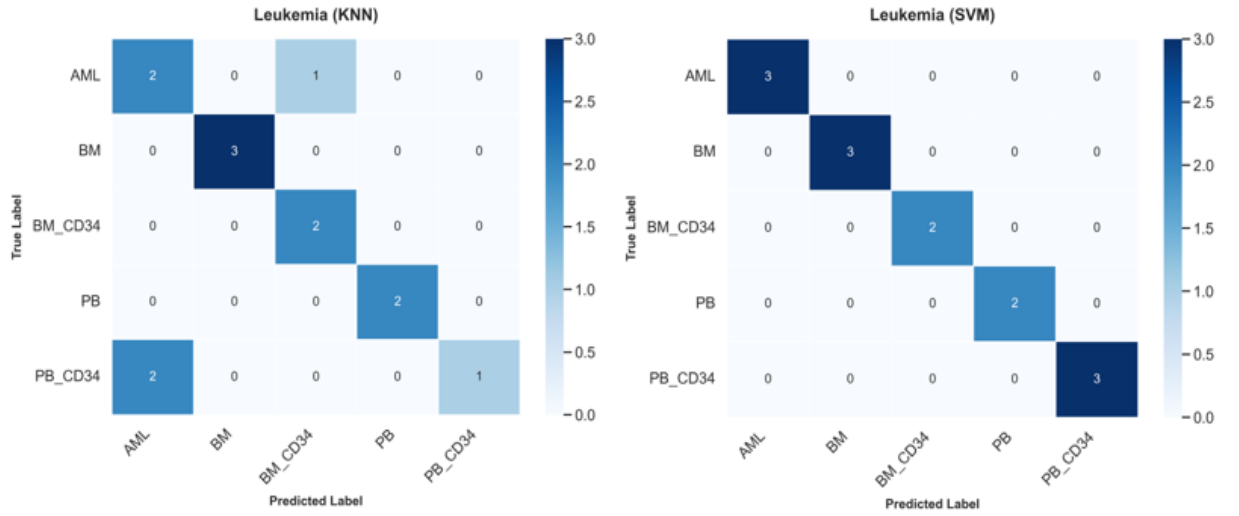

Figure 4. Confusion Matrix — Leukemia (Multi-class).

2. Golub Dataset: The Power of Dimensionality Reduction

The Golub dataset validated the proposed framework most effectively. The instance-based KNN classifier (73%) was overwhelmed by the high-dimensional noise, which is also known as the "Curse of Dimensionality." This made Euclidean distances less useful. SVM-RFE (93%), on the other hand, was able to cut thousands of irrelevant genes down to a short signature of 10 features.

This shows that discriminative models with built-in feature selection are much less sensitive to noise than distance-based methods.

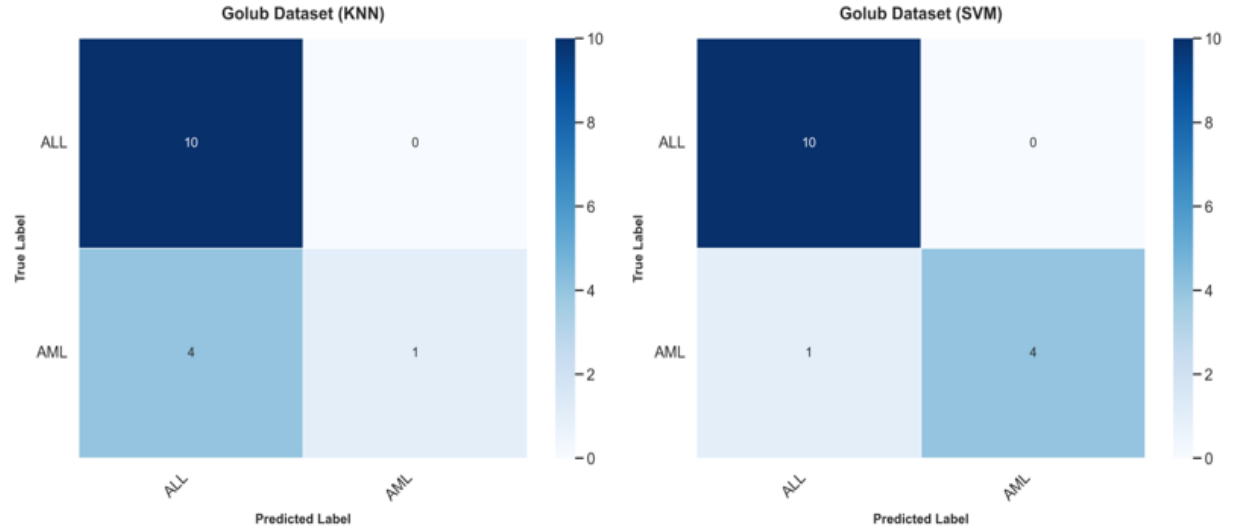

Figure 5. Confusion Matrix — Golub (Binary).

3. Prostate Cancer: Biological Relevance and Biomarkers

The SVM model got 97% accuracy on the Prostate dataset, missing just one sample. Importantly, it did this with only 10 genes, which is fewer than the 15+ needed by KNN. The SVM-RFE process consistently chooses genes like G2619 and G4212, which means that these genes are likely to be good discriminative features for classifying prostate cancer.

This lack of data has real-world clinical consequences: creating a diagnostic PCR test for 10 genes is much cheaper and faster than making one for a larger group of genes.

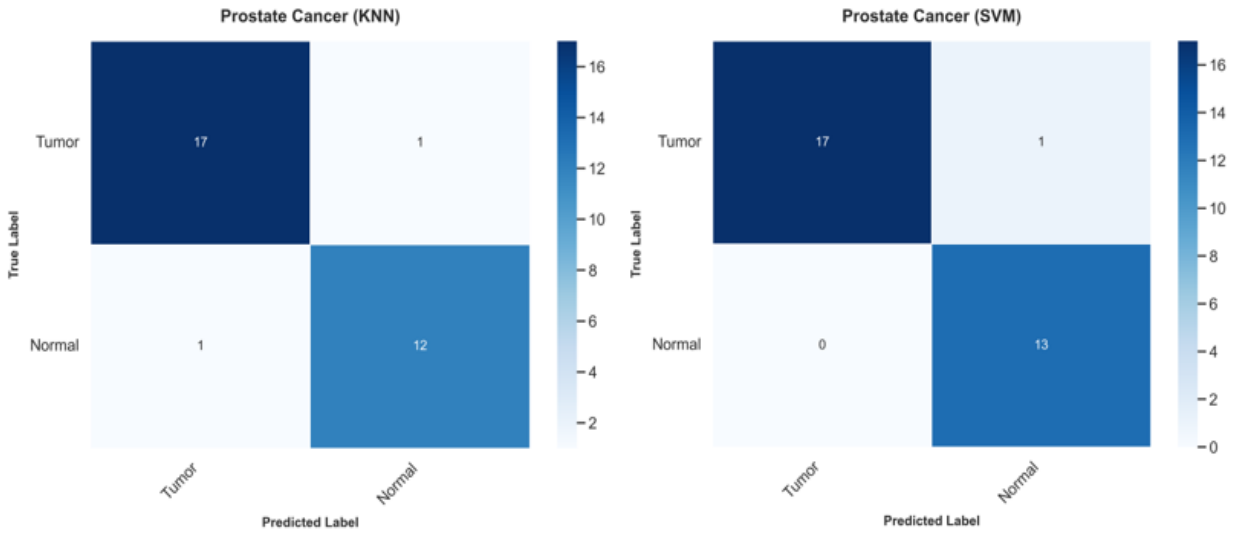

Figure 6. Confusion Matrix — Prostate (Binary).

4. Colon Cancer: Sample Size Limitations

The Colon dataset showed that both models reached a maximum accuracy of 69%.

This poor performance is probably because of the small-N, large-p setting, where there weren't enough training examples for the SVM to find a strong hyperplane. This made it biased toward the majority class (Benign).

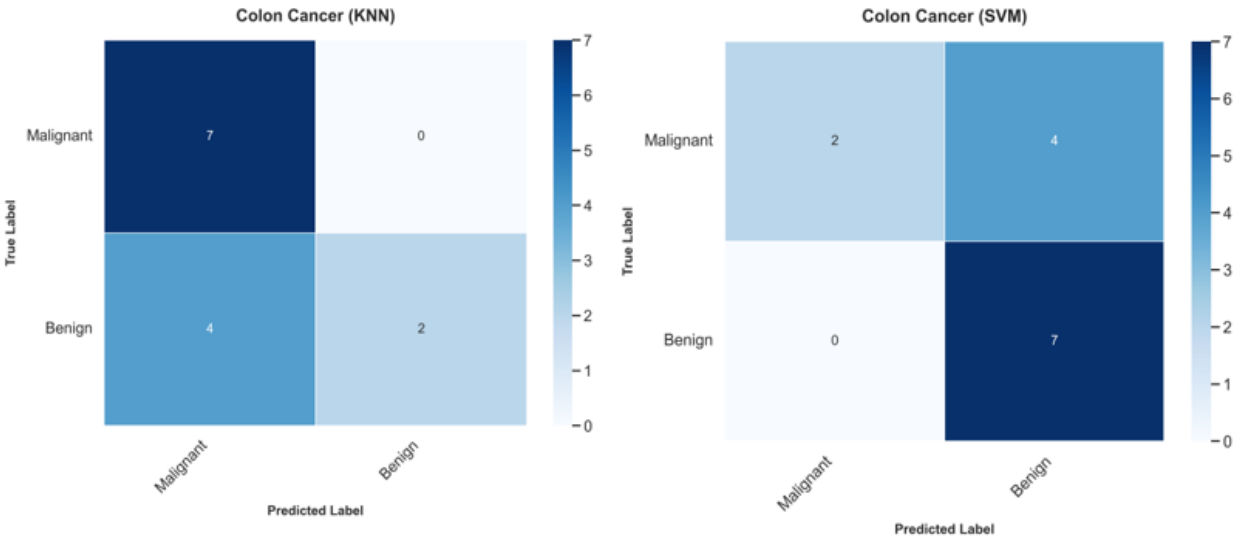

Figure 7. Confusion Matrix — Colon (Binary).

5. Brain Cancer: Robustness in Multi-class Settings

The Brain dataset was the hardest to work with. KNN got 61.5% of the answers right, but SVM-RFE got 66.7% of the answers right. This performance drop compared to other datasets is mostly because the stratified test set is small (about N ≈ 18) for a 5-class problem.

With only about 2–3 samples per class, a single misclassification can change the accuracy score by almost 8%. The confusion matrices show that SVM was a little better at classifying the Medulloblastoma subtype than KNN.

This supports SVM's ability to generalize better in high-dimensional, multi-class settings.

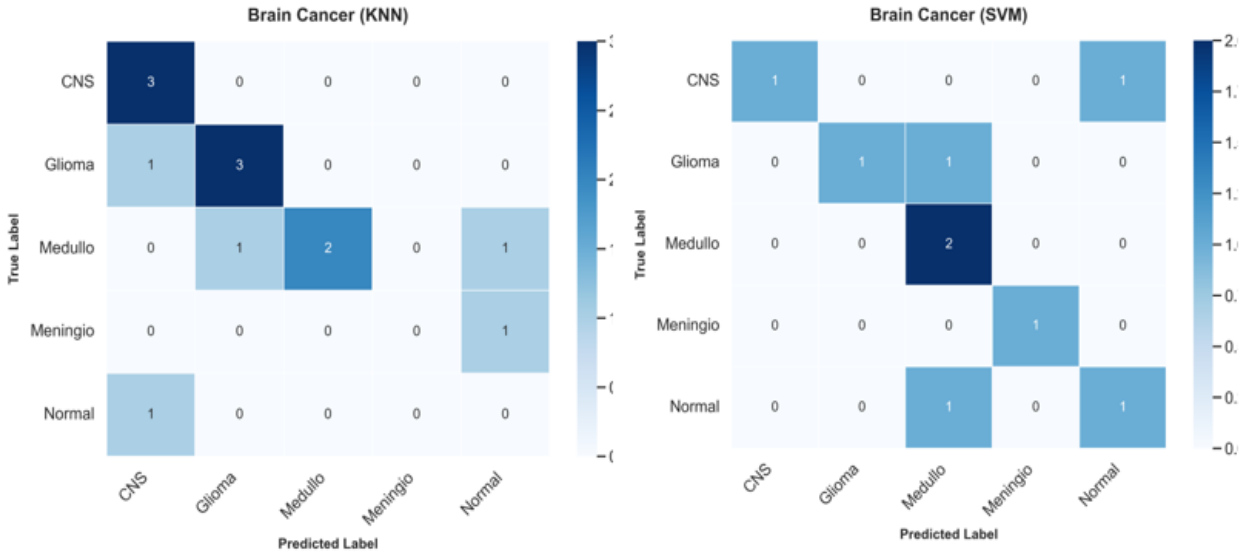

Figure 8. Confusion Matrix — Brain (Multi-class).

The experimental results show a clear order of performance. The SVM-RFE framework showed better stability, especially in datasets with a lot of noise (Golub) and a lot of different classes (Brain). KNN worked well as a baseline for simpler datasets that were well-separated (like Prostate), but it didn't work as well in "small N, large p" situations. The visual evidence from the confusion matrices shows that SVM's hyperplane-based decision logic, along with recursive feature elimination, is a better diagnostic tool for clinical settings where avoiding false negatives is very important.

C. Advanced Visual Analysis

This part adds a rigorous diagnostic analysis of the models' decision boundaries and learning dynamics to the quantitative evaluation.

We specifically isolate datasets that exhibited distinctive statistical characteristics—such as high-dimensional sparsity (Prostate) or class inhomogeneity (Brain)—to examine the underlying mechanisms responsible for the observed discrepancies in fit and generalization.

1. Receiver Operating Characteristic (ROC) Analysis

ROC curves were made to look at the balance between sensitivity and specificity. The SVM models always had higher Area Under the Curve (AUC) values than KNN, especially for the binary datasets. For example, the Prostate dataset had a very high AUC, almost 1.0, which showed that the model was very good at telling the difference between tumor samples with very few false positives.

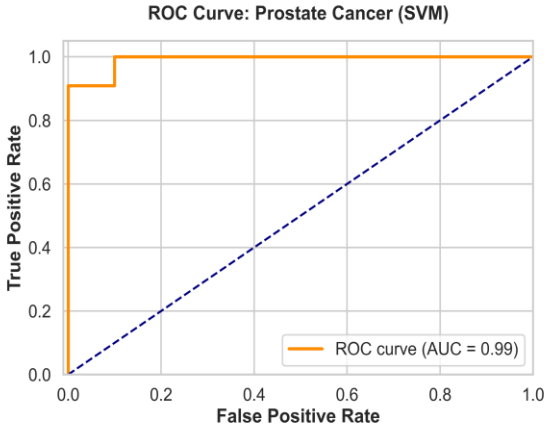

Figure 9. ROC Curves comparing SVM vs KNN Performance

2. Biological Feature Importance

One of the best things about the SVM-RFE wrapper is that it can rank genes based on how well they can tell the difference between things. The feature importance plots show that the genes with the most impact were chosen.

The top-ranked features for Prostate Cancer always included G2619, which indicates its potential as a discriminative biomarker.

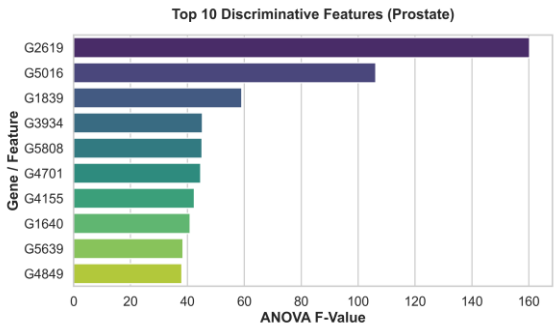

Figure 10: Top 10 Discriminative Features (SVM-RFE) - Prostate Dataset

3. Learning Curves and Data Scalability

The learning curves show the "N" limit that was talked about for the Colon and Brain datasets. The big difference between training and validation accuracy that doesn't go away shows that the models are overfitting, which means that they would greatly benefit from more training samples to stabilize the decision boundary.

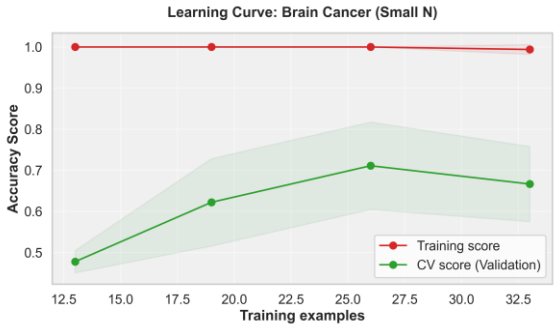

Figure 11: Learning Curves (Bias-Variance Analysis) - Colon Dataset

D. Synthesis of Experimental Results

In short, the experimental results show that there is a clear order of performance. The SVM-RFE framework showed better stability, especially in datasets with a lot of noise (Golub) and a lot of classes (Brain). KNN worked well as a baseline for simpler datasets that were well-separated (like Prostate), but it didn't work as well when there were "small N, large p" situations.

The confusion matrices show that the hyperplane-based decision logic of SVM, along with recursive feature elimination, is a more reliable diagnostic tool for clinical settings where it is very important to minimize false negatives.

VI. CONCLUSION

This study performed a comprehensive comparative analysis of K-Nearest Neighbors (KNN) and Support Vector Machines (SVM) for high-dimensional cancer gene-expression classification by utilizing univariate ANOVA and multivariate Recursive Feature Elimination (RFE). The SVM–RFE framework was clearly better than KNN–ANOVA across five benchmark datasets (Leukemia, Golub, Prostate, Colon, and Brain), with an average accuracy of about 88% compared to about 75% for KNN–ANOVA. The benefit was greatest in datasets with very high dimensionality, where SVM-RFE successfully removed extra genes and kept biological signals that were useful for diagnosis, making it much more reliable.

The research also showed that you can accurately classify cancer using small gene signatures of only 10–15 genes. This makes biomarker-based diagnostics more affordable. The differences in performance across datasets and the drop in performance in the small-sample Brain dataset show how important explainable AI and careful preprocessing are in biomedical machine learning. In general, the results show that SVM-RFE is a strong and clinically useful framework for genomic cancer diagnosis. They also stress the importance of careful validation and biologically based feature selection.

VII. FUTURE ENHANCEMENT

Future research will build on this comparison by looking into ensemble learning methods like Random Forests and Gradient Boosting (XGBoost) to reduce the differences seen in multi-class and small-sample datasets.

We also want to look into how deep learning architectures, like 1D-Convolutional Neural Networks (1D-CNNs) and Autoencoders, can be used to extract non-linear features from larger next-generation sequencing (NGS) datasets.

Finally, a crucial subsequent step entails working with clinical oncologists to biologically validate the identified sparse gene signatures (e.g., G2619 in prostate cancer) to evaluate their viability as translatable diagnostic biomarkers.
